**ABSTRACT:** The Svalbard–Barents ice sheet was predominantly a marine-based ice sheet and reconstructing the timing and rate of its decay during the last deglaciation informs predictions of future decay of marine-based ice sheets (e.g. West Antarctica). Records of ice-sheet change are routinely built with cosmogenic surface exposure ages, but in some regions, this method is complicated by the presence of isotopic inheritance yielding artificially old and erroneous exposure ages for the most recent deglaciation. We present 46  $^{10}\text{Be}$  ages from south-western Spitsbergen that, when paired with *in situ*  $^{14}\text{C}$  measurements ( $n=5$ ), constrain the timing of coastal deglaciation following the last glacial maximum.  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  measurements from bedrock along a ~400-m elevation transect reveal inheritance-skewed  $^{10}\text{Be}$  ages, whereas *in situ*  $^{14}\text{C}$  measurements constrain 400 m of ice-sheet thinning and coastal deglaciation at  $17.4 \pm 1.5$  ka. Our *in situ*  $^{14}\text{C}$ -dated transect, combined with three additional  $^{10}\text{Be}$ -dated coastal sites, show that the south-western margin of the Svalbard–Barents ice sheet retreated out of the Norwegian Sea between ~18 and 16 ka. *In situ*  $^{14}\text{C}$  measurements provide key chronological information on ice-sheet response to the last termination in cases where measurements of long-lived nuclides are compromised by isotopic inheritance. © 2018 John Wiley & Sons, Ltd.

**KEYWORDS:** cosmogenic nuclides; ice sheets; *in situ*  $^{14}\text{C}$ ; Quaternary; Svalbard.

## Introduction

Geological records that constrain the timing and magnitude of ice-sheet demise during the last deglaciation provide important insights into the response of ice sheets to a warming climate. At its maximum extent during the last glacial cycle, the Svalbard–Barents ice sheet (SBIS) was part of the broader Eurasian ice sheet complex with a sea-level equivalent of ~24 m (Hughes *et al.*, 2016). Resting at the north-western limit of the SBIS, the Svalbard Archipelago is one of the few terrestrial locations within the primarily marine-based SBIS footprint. Accordingly, much of our current understanding of how the SBIS evolved through the last glacial cycle is based on archives of ice-sheet change present on Svalbard (Fig. 1; Landvik *et al.*, 1998, 2014; Hormes *et al.*, 2013; Ingólfsson and Landvik, 2013; Eccleshall *et al.*, 2016). Gauging how the SBIS decayed at the end of the last glaciation can help identify mechanisms of global climate change and inform ice sheet models used to explore the sensitivity of marine-based ice sheets to various climatic and glaciological parameters (Stokes *et al.*, 2015; Patton *et al.*, 2016).

Cosmogenic nuclide measurements are often used to develop detailed chronologies of ice sheet and glacier change (e.g. Balco, 2011; Granger *et al.*, 2013; Ivy-Ochs and Briner, 2014). On Svalbard, there have been several efforts to

reconstruct SBIS behavior during the last glacial cycle using cosmogenic nuclides with mixed success. One limitation is that much of Svalbard does not host the quartz-bearing rocks required for  $^{10}\text{Be}$  measurements, and thus the geographical scope of cosmogenic nuclide-based measurements is relatively restricted. Nonetheless, the first  $^{10}\text{Be}$  ages from Svalbard were used to propose that ice-free regions in north-western Svalbard existed during the last glacial maximum (Landvik *et al.*, 2003). However, while  $^{10}\text{Be}$  ages older than ~75 ka defined the maximum SBIS thickness in NW Svalbard, these old  $^{10}\text{Be}$  ages do not preclude the presence of widespread and systematic isotopic inheritance on the landscape. Using the same approach, several  $^{10}\text{Be}$  ages from western Svalbard and Nordaustlandet help constrain the dimensions of the SBIS during the last glacial cycle (Hormes *et al.*, 2011, 2013; Gjermundsen *et al.*, 2013; Landvik *et al.*, 2013; Fig. 1). Most recently,  $^{10}\text{Be}$  and  $^{26}\text{Al}$  measurements from high-elevation bedrock suggest that Svalbard's alpine landscape has survived repeated glaciations through the Quaternary, suggestive of a minimally erosive ice sheet (Gjermundsen *et al.*, 2015). Although these studies place broad constraints on SBIS behavior through the last glacial cycle and longer, they also suffer from somewhat geographically and chronologically scattered  $^{10}\text{Be}$  ages, making it difficult to develop detailed millennial-scale chronologies of ice-sheet change. Collectively, these studies highlight a landscape that is challenging for developing cosmogenic-nuclide based chronologies of ice-sheet change, probably

**Figure 1.** Spitsbergen with locations referred to in the text and the 21 ka ice limit from Hughes et al. (2016; dashed line). KE – Kapp Ekholm, H – Hornsund, and IF – Isfjorden. Previously published radiocarbon (cal ka BP) and  $^{10}\text{Be}$  ages across Spitsbergen from previous studies constraining ice margin position are presented in two groups: (i) ages that mark the initial timing of retreat or thinning of the ice margin from the Last Glacial Maximum (LGM) extent (white ovals with black text), and (ii) oldest coastal ages that constrain deglaciation following the LGM maximum extent and deglaciation of the present coastline (black ovals/white text). Location numbers are linked to Table 4; see Table 4 for sample details and references. Locations and  $^{10}\text{Be}$  ages marked with stars and boxes are from this study. Isfjorden and Hornsund transects from Fig. 4 are marked with black lines. Base and inset maps are from Jakobsson et al. (2012). [Colour figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

due to the widespread presence of non-erosive cold-based ice and its variable imprint on the landscape (Landvik et al., 2014).

Surface exposure dating in glacial landscapes relies on the assumption that cosmogenic nuclides that accumulated on the landscape before the most recent episode of exposure have been removed by ~2–3 m of subglacial erosion during the latest interval of ice cover. In settings dominated by warm-based and erosive ice, this assumption is typically valid, but at high-latitude locations, minimally erosive polythermal and cold-based ice can result in cosmogenic nuclide datasets that are influenced by isotopic inheritance (e.g. Håkansson et al., 2008; Balco et al., 2014; Young et al., 2016). Isotopic inheritance occurs when ice is unable to erode through the ~2–3 m of rock required to reset the cosmogenic clock between periods of surface exposure and the resulting nuclide concentration is an aggregate of two or more distinct periods of exposure. Inheritance is also possible within landscapes where despite 2–3 m of erosion during the latest interval of glaciation, deep subsurface nuclide accumulation in periods of prolonged surface exposure between

glaciations results in excess nuclide inventories that pre-date the most recent period of ice cover (Briner et al., 2016).

Whereas long-lived or stable nuclides such as  $^{10}\text{Be}$  ( $t_{1/2} = 1.387$  Ma; Chmeleff et al., 2010) must be removed from the landscape via sufficient subglacial erosion, *in situ*  $^{14}\text{C}$  is unique because its relatively short half-life ( $t_{1/2} = 5730$  years) allows for previously accumulated *in situ*  $^{14}\text{C}$  to decay away to undetectable levels after ~30 ka of simple burial of a surface by ice without the aid of subglacial erosion. *In situ*  $^{14}\text{C}$  measurements are perhaps most powerful when paired with  $^{10}\text{Be}$  to resolve complex exposure–burial histories (e.g. Goehring et al., 2011), but *in situ*  $^{14}\text{C}$  measurements are also particularly attractive in environments characterized by minimally erosive ice that is not capable of resetting the cosmogenic clock between periods of exposure. Measuring several nuclides in conjunction yields a more complete quantitative understanding of ice-sheet fluctuations over multiple time-scales, but *in situ*  $^{14}\text{C}$  measurements are also well-suited to constrain the timing of the last deglaciation in settings where long-lived nuclides such as  $^{10}\text{Be}$  run a much higher risk of carrying inheritance from prior exposure (e.g.

Briner *et al.*, 2014; Johnson *et al.*, 2017). Despite its potential, *in situ*  $^{14}\text{C}$  is rarely used because of the difficulty of extracting  $^{14}\text{C}$  from the mineral quartz in geological samples (e.g. Lifton *et al.*, 2001; Balco *et al.*, 2016).

We present 46  $^{10}\text{Be}$  ages, five *in situ*  $^{14}\text{C}$  ages and five  $^{26}\text{Al}$  ages from four sites in south-western Spitsbergen to constrain the timing of coastal deglaciation following the last glacial maximum. A component of our  $^{10}\text{Be}$  ages are influenced by isotopic inheritance, but our population of  $^{10}\text{Be}$  ages is sufficiently large to constrain the timing of coastal deglaciation in south-western Spitsbergen. Combined *in situ*  $^{10}\text{Be}$ ,  $^{14}\text{C}$  and  $^{26}\text{Al}$  in five bedrock samples along a ~400-m elevation transect reveal that  $^{10}\text{Be}$  and  $^{26}\text{Al}$  concentrations yield an ambiguous timing of deglaciation and a complex long-term exposure history but corresponding *in situ*  $^{14}\text{C}$  measurements robustly constrain millennial-scale ice-sheet thinning.

## Setting and methods

Our study area is Hornsund (76.97°N, 15.70°E), located in south-western Spitsbergen (Figs 1 and 2). Several independent

glaciers feed into the primary Hornsund channel and, at present, ~800 km<sup>2</sup> of Hornsund's ~1200-km<sup>2</sup> drainage basin is glaciated with glacier retreat during the observational record averaging ~70 m a<sup>-1</sup> (Błaszczyk *et al.*, 2013). At the head of Hornsund, a tidewater glacier is currently located ~13 km east of its late Holocene maximum extent, which is marked by a prominent moraine that was emplaced at Treskelen just before  $1.9 \pm 0.3$  ka based on recent  $^{10}\text{Be}$  ages ( $n=4$ ; Philipps *et al.*, 2017). During the last glacial cycle, Hornsund hosted an SBIS outlet glacier that was part of the western margin of the SBIS. The western SBIS is thought to have advanced out to the continental shelf three times during the last glacial cycle during Marine Isotope Stage (MIS) 5d, MIS 5b, and MIS 2 with retreat from the outer shelf underway as early as ~23–20 ka (Mangerud *et al.*, 1998; Jessen *et al.*, 2010; Hormes *et al.*, 2013; Eccleshall *et al.*, 2016). A single minimum limiting radiocarbon age from near Hornsund indicates that by ~12.1 cal ka BP ice was less extensive than it is today (Birkenmajer and Olsson, 1998; Hormes *et al.*, 2013). The long-term pattern of SBIS advance and retreat in western Svalbard is largely based on the Kapp Ekholm sediment section located at the inner reaches of Isfjorden,

**Figure 2.** Ice margin constraints at Hornsund (Norwegian Polar Institute; [toposvalbard.npolar.no/](http://toposvalbard.npolar.no/); collected in 2011). Individual  $^{10}\text{Be}$  ages from bedrock are shown in black text with white boxes; up-fjord erratics on the Treskelen Peninsula are displayed in white text with black boxes. Only the mean *in situ*  $^{14}\text{C}$  and  $^{10}\text{Be}$  age from the Torbjørnsenfjellet ( $n=5$ ) and Wurmbrandegga ( $n=6$ ; one outlier removed) elevation transects are shown (Fig. 3). The minimum-limiting radiocarbon age just north of Hornsund is in green (U-2972;  $12\,100 \pm 320$  cal ka BP; Birkenmajer and Olsson, 1998; Table 4). [Colour figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

which displays alternating units of glacial till and marine sediments (Fig. 1). Because Kapp Ekholm is situated only ~14 km from modern ice, the marine sediment units mark intervals when Svalbard glaciers were probably not much larger than today (Mangerud *et al.*, 1998; Eccleshall *et al.*, 2016).

We collected 46 samples for  $^{10}\text{Be}$  dating, five samples for  $^{26}\text{Al}$  measurement and five samples for *in situ*  $^{14}\text{C}$  measurements along the south-western coast of Spitsbergen. Thirty-four  $^{10}\text{Be}$  samples are from the Hornsund region and are divided into four distinct groups (Figs 1 and 2): (i) a series of nunatak and bedrock ridges ( $n=18$ ), (ii) an elevation transect at Torbjørnsenfjellet on the north side of Hornsund (bedrock;  $n=5$ ; Fig. 3A), (iii) an elevation transect at Wurmbrandegga on the south side of Hornsund (bedrock;  $n=7$ ; Fig. 3B), and (iv) boulders perched on a bedrock ridge adjacent to, but beyond, the late Holocene ice extent at Treskelen ( $n=4$ ). We measured *in situ*  $^{14}\text{C}$  and  $^{26}\text{Al}$  in each bedrock sample from the Torbjørnsenfjellet elevation transect. We also collected four bedrock samples from surfaces immediately outboard of the late Holocene terminal moraine (<150 m) at Scottbreen (77.54°N, 14.36°E) located ~70 km north-west of Hornsund (Fig. 1). Lastly, we collected four ridgeline bedrock samples from Fløyfjellet (77.41°N, 14.09°E) located ~60 km north-west of Hornsund and four bedrock samples from summits near Torellbreen (77.31°N, 14.09°E) located between Fløyfjellet and Hornsund (Fig. 1).

Samples were collected in 2013 and 2014 with a hammer and chisel, and a Trimble GeoXT and Tempest antenna GPS receiver with a vertical uncertainty of  $\pm 0.5$  m was used to record sample location and elevation. A handheld clinometer was used to measure topographic shielding by the surrounding topography.  $^{10}\text{Be}$  samples were processed at the Buffalo Cosmogenic Laboratory ( $n=29$ ), Lamont-Doherty Earth Observatory (LDEO) Cosmogenic Nuclide Laboratory ( $n=13$ ;  $n=5$   $^{26}\text{Al}$  samples), and the Scottish Universities Environmental Research Centre (SUERC;  $n=4$ ) following standard extraction methods for  $^{10}\text{Be}$  and  $^{26}\text{Al}$  (Schaefer *et al.*, 2009). *In situ*  $^{14}\text{C}$  samples were processed at LDEO and measured  $^{14}\text{C}$  concentrations are blank-corrected using a long-term laboratory blank (Goehring *et al.*, 2014; see Tables 2 and 3). Accelerator mass spectrometric measurements for LDEO and Buffalo samples were made at Lawrence Livermore National Laboratory – Center for Accelerator Mass Spectrometry, and the remaining samples were measured at SUERC (Table 1). Surface exposure ages were calculated using the Arctic ( $^{10}\text{Be}$  and  $^{26}\text{Al}$ ) and western Greenland ( $^{14}\text{C}$ ) production rate calibration datasets (Young *et al.*, 2013, 2014) and ‘Lm’ scaling (Lal, 1991; Stone, 2000). Ages are calculated using version 3 of the exposure age calculator found at <https://hess.ess.washington.edu/>, that implements an updated treatment of muon-based nuclide production (Balco *et al.*, 2008; Balco, 2017). We do not correct

<sup>a</sup>Samples processed at Buffalo and LDEO were measured at Lawrence Livermore National Laboratory – Center for Accelerator Mass Spectrometry (CAMS). Samples processed at SUERC were measured at SUERC AMS Laboratory. All ratios are reported relative to 07KNDSTD with a reported ratio of  $2.85 \times 10^{-12}$  using a  $^{10}\text{Be}$  half-life of  $1.36 \times 10^6$  years (Nishiizumi *et al.*, 2007).

<sup>b</sup> $^{10}\text{Be}$  concentrations are blank corrected using batch-specific process blanks. LDEO samples are blank corrected using values of 8259 ± 3148 atoms (TORB samples) and 3842 ± 539 atoms ( $n = 2$ ; FLO, FAN, ARD samples);  $^{10}\text{Be}$  concentrations for all SUERC samples are blank corrected using a value of 37999 ± 537 atoms; Buffalo samples are blank corrected using values of 48599 ± 5588 atoms (SCO-13, SCO-15, GUL-3, JAHN-1 samples), 33523 ± 9022 atoms (ORV-1, ORV-2, ORV-3, NORD-1 samples), 56575 ± 24289 atoms (BRATT-1, JAHN-2 samples), 29873 ± 1944 atoms (BRATT-3, GUL-1, GUL-2, SLY-1 samples), 33430 ± 5180 atoms (SCO-12, SCO-14, SLY-2 samples), 60094 ± 10954 atoms (BARA-1, WBE-03, WBE-04, WBE-05, WBE-06, WBE-07 samples), and 37093 ± 9868 atoms (WBE-01 and WBE-02 samples).

All ages are calculated using version 3 of the calculator code found at <https://hess.ess.washington.edu/> (Balco *et al.*, 2008; Balco, 2017), the 'Arctic'  $^{10}\text{Be}$  production rate (Young *et al.*, 2013), standard atmosphere and pressure 'std', a rock density of  $2.65 \text{ g cm}^{-3}$ , and assumes no erosion.

nuclide concentrations for snow-cover or erosion; samples are primarily from windswept locations and many sampled surfaces displayed primary glacial features. In addition, we make no correction for isostatic rebound because the effects of uplift on nuclide production are probably offset by atmospheric compression, although these effects are difficult to quantify (Staiger *et al.*, 2007). Individual exposure ages are presented and discussed with 1-sigma analytical uncertainties, and when comparing our results to independently dated records of ice sheet or environmental change, the production rate uncertainty is propagated through in quadrature.

## Results

Four individual  $^{10}\text{Be}$  ages at Scottbreen are  $18.8 \pm 0.5$ ,  $17.9 \pm 0.3$ ,  $16.3 \pm 0.3$  and  $17.8 \pm 0.4$  ka (all bedrock). At Fløyfjellet, four individual  $^{10}\text{Be}$  ages are  $16.2 \pm 0.4$ ,  $16.2 \pm 0.4$ ,  $15.9 \pm 0.4$  and  $15.3 \pm 0.4$  ka (all bedrock), and at Torellbreen, four additional  $^{10}\text{Be}$  ages are  $23.0 \pm 0.5$ ,  $17.3 \pm 0.5$ ,  $16.0 \pm 0.3$  and  $14.3 \pm 0.3$  ka (all bedrock). At Hornsund, the coastal nunatak and ridgeline  $^{10}\text{Be}$  ages span  $5.6 \pm 0.1$  to  $36.5 \pm 0.7$  ka ( $n = 18$ ; bedrock). The Wurmbrandegga elevation transect has  $^{10}\text{Be}$  ages ranging between  $10.9 \pm 0.3$  and  $13.8 \pm 0.3$  ka ( $n = 7$ ; bedrock), and the Torbjørnsenfjellet elevation transect has  $^{10}\text{Be}$  ages ranging from  $16.0 \pm 0.3$  to  $36.3 \pm 0.6$  ka ( $n = 5$ ; bedrock). The up-fjord  $^{10}\text{Be}$  ages from erratic boulders perched on bedrock range from  $12.6 \pm 0.4$  to  $15.4 \pm 0.9$  ka ( $n = 4$ ). Lastly,  $^{26}\text{Al}$  and *in situ*  $^{14}\text{C}$  ages at Torbjørnsenfjellet range from  $17.2 \pm 1.1$  to  $35.8 \pm 1.8$  ka and  $16.7 \pm 2.9$  to  $18.5 \pm 2.7$  ka, respectively (Tables 1–3). Measured  $^{26}\text{Al}/^{10}\text{Be}$  ratios range from  $7.38 \pm 0.64$  to  $5.77 \pm 0.38$ .

## Multiple nuclides constrain the timing of deglaciation and erosion regimes

### Scottbreen, Fløyfjellet and Torellbreen

The mean of four  $^{10}\text{Be}$  ages at Scottbreen is  $17.7 \pm 1.2$  ka (production rate uncertainty included) and it is tempting to use this age constraint as the timing of local coastal deglaciation. However, these four samples are all from bedrock locations that are in close proximity to one another (~300 m distance and 38 m elevation) and are located immediately outside Scottbreen's historical maximum extent. Landscapes positioned near glacial maxima that spend a large proportion of a glacial cycle ice free may be affected by small, uniform amounts of isotopic inheritance that yield consistent, but slightly too old  $^{10}\text{Be}$  ages (Briner *et al.*, 2016). Because the Scottbreen samples are from such close proximity to each other, it is possible these  $^{10}\text{Be}$  bedrock ages simply constrain a local  $^{10}\text{Be}$  inventory that contains a small, and uniform, amount of isotopic inheritance. In addition, the age  $17.7 \pm 1.2$  ka would indicate that Scottbreen retreated within its late Holocene maximum extent rather early following the last glacial maximum. Nonetheless, while small amounts of inheritance may be influencing our Scottbreen  $^{10}\text{Be}$  ages, we tentatively use  $17.7 \pm 1.2$  ka as the timing of local deglaciation. At Fløyfjellet, all  $^{10}\text{Be}$  ages overlap at 1-sigma, indicating that deglaciation occurred at  $15.9 \pm 0.7$  ka. The four  $^{10}\text{Be}$  ages at Torellbreen are more scattered (Table 1), but the individual  $^{10}\text{Be}$  ages of  $14.3 \pm 0.3$ ,  $16.0 \pm 0.3$  and  $17.3 \pm 0.5$  ka (mean =  $15.9 \pm 1.5$  ka) are consistent with the timing of deglaciation at Fløyfjellet and Scottbreen. Combined,  $^{10}\text{Be}$  ages indicate that deglaciation at Scottbreen, Fløyfjellet and Torellbreen occurred at  $17.7 \pm 1.2$ ,  $15.9 \pm 0.7$  and  $15.9 \pm 1.5$  ka, respectively (Fig. 1).

**Table 2.** *In situ*  $^{14}\text{C}$  extraction details.

| Sample   | Date extracted | Quartz (g) | $V_{\text{CO}_2}$ (cc STP) | $V_{\text{dilute}}$ (cc STP) | CAMS no. | $F_m$ measured  | $^{14}\text{C}$ blank-corrected (atoms $\text{g}^{-1}$ ) | $^{14}\text{C}$ age – Lm (ka) | $^{14}\text{C}$ age – LSD (ka) |
|----------|----------------|------------|----------------------------|------------------------------|----------|-----------------|----------------------------------------------------------|-------------------------------|--------------------------------|
| 14TORB-1 | 3/4/15         | 5.1234     | 0.2576 ± 0.0030            | 1.5901 ± 0.0184              | 170000   | 0.0259 ± 0.0002 | 208 248 ± 8111                                           | 18.5 ± 2.7                    | 19.1 ± 2.9                     |

| 14TORB-3 | 22/4/15        | 5.0427     | 0.7704 ± 0.0089            | 1.4295 ± 0.0165              | 170152   | 0.0214 ± 0.0002 | 146 890 ± 7942                                           | 17.3 ± 3.2                    | 17.3 ± 3.2                     |
| 14TORB-4 | 22/2/16        | 5.0307     | 0.3336 ± 0.0038            | 1.6875 ± 0.0194              | 173884   | 0.0186 ± 0.0001 | 149 829 ± 8358                                           | 16.9 ± 3.1                    | 16.9 ± 3.1                     |
| 14TORB-5 | 5/5/15         | 5.1089     | 0.5360 ± 0.0062            | 0.9921 ± 0.0115              | 173356   | 0.0298 ± 0.0003 | 141 823 ± 7643                                           | 16.7 ± 2.9                    | 16.6 ± 2.9                     |

All samples are blank corrected using an LDEO long-term value of  $112.55 \pm 36.83 \times 10^3$   $^{14}\text{C}$  atoms ( $n = 23$ ).

Sample weight, gas volume after carbon extraction from quartz ( $V_{\text{CO}_2}$ ) and after addition of  $^{14}\text{C}$ -free dilution gas ( $V_{\text{dilute}}$ ), cc STP cubic centimeters at standard temperature and pressure, measured fraction modern ( $F_m$  the  $^{14}\text{C}/^{13}\text{C}$  ratio of the sample vs. that of a standard, both corrected to  $\delta^{13}\text{C}$  25‰ VPDB and to 1950 CE), blank-corrected  $^{14}\text{C}$  concentrations with analytical uncertainties. We report  $^{14}\text{C}$  ages using 'Lm' (Lal, 1991; Stone, 2000) and 'LSD' (Lifton et al., 2014) scaling.

The consistency between the timing of deglaciation at Scottbreen ( $17.7 \pm 1.2$  ka), Fløyfjellet ( $15.9 \pm 0.7$  ka) and Torellbreen ( $15.9 \pm 1.5$  ka), which all post-date the last glacial maximum, is suggestive of  $^{10}\text{Be}$  ages that are accurately recording the timing of deglaciation and are not influenced by inheritance. Moreover,  $^{10}\text{Be}$  ages at all three locations are solely from bedrock, suggesting that a warm-based SBIS was able to erode through the ~2 m of rock required to reset the cosmogenic clock along Spitsbergen's south-western coast. Ultimately, we cannot rule out that our  $^{10}\text{Be}$  measurements from Scottbreen, Fløyfjellet and Torellbreen are systematically influenced by deep subsurface nuclide accumulation during periods of prolonged surface exposure and contain a small amount of isotopic inheritance (Briner *et al.*, 2016). However, similar  $^{10}\text{Be}$  ages that are influenced by systematic deep subsurface nuclide accumulation would probably require near-identical exposure histories and total erosion depths during periods of ice cover across all three sites. We prefer the more likely scenario where the consistency in  $^{10}\text{Be}$  ages at Scottbreen, Fløyfjellet and Torellbreen simply reflects the similar timing of deglaciation across these sites and the erosional efficiency of a warm-based SBIS (Fig. 1).

### Hornsund

Constraining the timing of initial deglaciation at Hornsund is more challenging. Here, we consider  $^{10}\text{Be}$  ages within the context of their morphostratigraphic position. A series of ages from coastal nunataks and ridges range from  $5.6 \pm 0.1$  to  $36.5 \pm 0.7$  ka, show no clear trend with elevation as would be expected with glacier thinning, and adjacent samples from similar elevations often have drastically different ages (Fig. 2; black text/white boxes; Table 1). A number of coastal ages are older than 20 ka and there appears to be a mode of  $^{10}\text{Be}$  ages centered at ~30–35 ka (Fig. 2). These ages could constrain an initial pulse of ice-sheet thinning or an episode of MIS 3 deglaciation followed by non-erosive MIS 2 burial. However, three  $^{10}\text{Be}$  ages of  $34.5 \pm 0.6$ ,  $36.4 \pm 0.7$  and  $36.5 \pm 0.7$  ka are from ~110 masl, whereas slightly inland there are  $^{10}\text{Be}$  ages of  $18.7 \pm 0.3$  and  $17.3 \pm 0.6$  ka from ~750 and 680 masl, respectively. It is possible that these younger ages inland were affected by post-deglaciation mass wasting events, but our ages of >30 ka that pre-date the last deglaciation rest in a region where subglacial erosion during periods of ice cover was probably not as intense as in the primary Hornsund channel (Fig. 2). The large spread in  $^{10}\text{Be}$  ages and a  $^{10}\text{Be}$  age–elevation relationship that violates simple morphostratigraphy is probably due to a combination of isotopic inheritance in low-erosion zones, combined with sampling bedrock surfaces where the original post-deglaciation surface has not been preserved. Radiocarbon ages from marine sediments in a variety of settings indicate that the ice sheet extended ~70 km west of Hornsund to the continental shelf edge until ~23 ka (Fig. 1). Moreover, a recent synthesis of Eurasian ice sheet extent suggests that ice in the Barents sector was at its maximum between ~23 and 20 ka, making it unlikely that the Hornsund mouth deglaciated at or before ~23–21 ka as suggested by several of our  $^{10}\text{Be}$  ages older than 23 ka (i.e. 35 ka mode in  $^{10}\text{Be}$  ages; Figs 1 and 2; Hughes *et al.*, 2016).

### Torbjørnsenfjellet

$^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  measurements from the Torbjørnsenfjellet elevation transect constrain the timing of initial deglaciation of the Hornsund fjord mouth. In descending elevational order: the highest elevation sample (TORB-1; 633 m asl) has a  $^{10}\text{Be}$  age of  $16.0 \pm 0.3$  ka followed by  $^{10}\text{Be}$  ages of  $18.3 \pm 0.3$

**Table 3a.** *In situ*  $^{14}\text{C}$  blank data.

| Sample         | $V_{\text{CO}_2}$ (cc STP) | $V_{\text{dilute}}$ (cc STP) | CAMS no. | $F_m$ measured      | $^{14}\text{C}$ ( $10^3$ atoms) |
|----------------|----------------------------|------------------------------|----------|---------------------|---------------------------------|
| Blank 11-20-14 | $0.01643 \pm 0.00019$      | $1.446 \pm 0.017$            | 168812   | $0.0048 \pm 0.0001$ | $107.03 \pm 13.60$              |
| Blank 1-15-15  | $0.01295 \pm 0.00015$      | $1.391 \pm 0.016$            | 168813   | $0.0048 \pm 0.0001$ | $100.87 \pm 13.18$              |
| Blank 3-10-15  | $0.01202 \pm 0.00014$      | $1.351 \pm 0.015$            | 169702   | $0.0061 \pm 0.0001$ | $153.24 \pm 12.92$              |
| Blank 4-17-15  | $0.01346 \pm 0.00016$      | $1.424 \pm 0.016$            | 170151   | $0.0045 \pm 0.0001$ | $89.66 \pm 13.48$               |
| Blank 9-16-15  | $0.01318 \pm 0.00015$      | $1.373 \pm 0.016$            | 172629   | $0.0063 \pm 0.0001$ | $164.18 \pm 13.17$              |
| Blank 3-2-16   | $0.01401 \pm 0.00016$      | $1.403 \pm 0.016$            | 173886   | $0.0040 \pm 0.0001$ | $67.01 \pm 13.22$               |

We report all blank measurements completed since November 2014. The previous LDEO long-term blank was  $118.09 \pm 39.28 \times 10^3$   $^{14}\text{C}$  atoms and included blanks up to September 2013 (Young *et al.*, 2014). The updated LDEO long-term blank value that includes the above measurements is  $112.55 \pm 36.83 \times 10^3$   $^{14}\text{C}$  atoms ( $n=23$ ).

**Table 3b.** LDEO CRONUS-A *in situ*  $^{14}\text{C}$  data.

| Sample           | Quartz (g) | $V_{\text{CO}_2}$ (cc STP) | $V_{\text{dilute}}$ (cc STP) | CAMS no. | $F_m$ measured      | $^{14}\text{C}$ ( $10^3$ atoms $\text{g}^{-1}$ ) |
|------------------|------------|----------------------------|------------------------------|----------|---------------------|--------------------------------------------------|
| CRONUS-A-3-24-15 | 4.8795     | $0.1122 \pm 0.0013$        | $1.470 \pm 0.017$            | 169935   | $0.0826 \pm 0.0003$ | $735.89 \pm 12.27$                               |
| CRONUS-A-4-16-16 | 3.6393     | $0.0553 \pm 0.0006$        | $1.439 \pm 0.017$            | 173885   | $0.0618 \pm 0.0004$ | $706.23 \pm 14.53$                               |
| CRONUS-A-5-19-16 | 3.6502     | $0.0512 \pm 0.0006$        | $1.423 \pm 0.016$            | 174602   | $0.0624 \pm 0.0002$ | $696.69 \pm 13.78$                               |

CRONUS-A measurements since October 2013. Values are consistent with a previously reported long-term CRONUS-A value of  $655.17 \pm 30.87 \times 10^3$   $^{14}\text{C}$  atoms  $\text{g}^{-1}$  (Young *et al.*, 2014). We note, however, that beginning with the CRONUS-A-3-24-15 extraction, we started working with a new aliquot of the CRONUS-A quartz standard.

ka (TORB-2; 515 m),  $36.3 \pm 0.6$  ka (TORB-4; 279 m),  $25.8 \pm 0.4$  ka (TORB-3; 252 m) and  $20.1 \pm 0.3$  ka (TORB-5; 225 m). The oldest ages rest in the middle of the elevation transect and the youngest age is also the highest elevation sample (Fig. 2). This  $^{10}\text{Be}$  age–elevation distribution reveals that  $^{10}\text{Be}$  ages are not accurately recording the timing of glacier thinning and deglaciation because  $^{10}\text{Be}$  ages do not get younger with decreasing elevation nor are they statistically indistinguishable, the latter of which would suggest rapid deglaciation of all sample sites (i.e. within dating resolution). Corresponding *in situ*  $^{14}\text{C}$  ages, however, display a much different age–elevation relationship. Paired  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  ages for TORB-1 and TORB-2, our highest elevation samples, statistically overlap at 1-sigma, indicating these samples do not contain inherited  $^{10}\text{Be}$  (Fig. 3; Table 1). The mid-transect samples with  $^{10}\text{Be}$  ages of  $36.3 \pm 0.6$  ka (TORB-4) and  $25.8 \pm 0.4$  ka (TORB-3) have significantly younger  $^{14}\text{C}$  ages of  $16.9 \pm 3.1$  and  $17.3 \pm 3.2$  ka, indicating that they contain a  $^{10}\text{Be}$  inventory equating to  $19.4 \pm 3.2$  and  $8.5 \pm 3.2$  ka of excess  $^{10}\text{Be}$  that accumulated during a previous period(s) of surface exposure. The lowest elevation sample (TORB-5) has a  $^{10}\text{Be}$  age of  $20.1 \pm 0.3$  ka and a  $^{14}\text{C}$  age  $16.7 \pm 2.9$  ka. We note that the 1-sigma analytical uncertainties of our *in situ*  $^{14}\text{C}$  measurements range from 4 to 7%, but that these measurements equate to exposure ages with internal uncertainties that range from  $\sim 15$  to 23%. Uncertainties range from  $\sim 15$  to 23% because our measured concentrations intersect the  $^{14}\text{C}$  production–time curve where small changes in  $^{14}\text{C}$  concentration equate to large changes in exposure age as one approaches surface saturation (nuclide production = decay; Table 2). Regardless, our *in situ*  $^{14}\text{C}$  measurements are able to quantify inherited  $^{10}\text{Be}$  in three of our five transect samples and, moreover, *in situ*  $^{14}\text{C}$  ages are statistically indistinguishable and average  $17.4 \pm 0.7$  ka ( $n=5$ ; Fig. 2; Fig. 3; Table 2). When accounting for the uncertainty in the production-rate calibration dataset, our  $^{14}\text{C}$  measurements reveal glacier thinning across our sample sites at the Hornsund mouth at  $17.4 \pm 1.5$  ka (7.5%; Young *et al.*, 2014).

Whereas paired  $^{10}\text{Be}$ – $^{14}\text{C}$  measurements at Torbjørnsenfjellet constrain the amount of isotopic inheritance and timing of deglaciation to  $17.4 \pm 1.5$  ka, paired  $^{26}\text{Al}$ – $^{10}\text{Be}$  measurements offer a long-term perspective of surface exposure and burial of the Torbjørnsenfjellet ridgeline. TORB-1 and TORB-2, which have statistically identical  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  ages, have  $^{26}\text{Al}/^{10}\text{Be}$  ratios consistent with constant exposure (Fig. 4; Table 1). Our mid-transect samples (TORB-4 and TORB-3) contain inherited  $^{10}\text{Be}$  and measured  $^{26}\text{Al}/^{10}\text{Be}$  ratios suggest some degree of prolonged burial (Fig. 4). Although the TORB-5  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  ages overlap at 2-sigma, suggestive of continuous exposure, the corresponding  $^{26}\text{Al}/^{10}\text{Be}$  ratio of  $5.77 \pm 0.38$  is inconsistent with constant exposure. Because all the transect *in situ*  $^{14}\text{C}$  ages are statistically identical and constrain the most recent period of exposure, we use the average *in situ*  $^{14}\text{C}$  age to quantify the exposure–burial history of the Torbjørnsenfjellet samples sites before the last  $\sim 17.4$  ka. Specifically, we subtract 17.4 ka worth of exposure from each paired  $^{26}\text{Al}$ – $^{10}\text{Be}$  measurement suggestive of non-continuous exposure (i.e.  $\text{Al}/\text{Be} < 6.75$ ; TORB-3, -4, -5) to quantify pre-17.4 ka exposure and burial at each sample location (Fig. 4). At TORB-5, our approach results in subtracting more  $^{26}\text{Al}$  than what was measured, but points to the presence of a small amount of excess  $^{10}\text{Be}$ , equating to  $3.4 \pm 2.9$  kyr of exposure. The corrected ratios for our mid-transect samples reveal a significant amount of pre-17.4 ka surface burial equating to  $\sim 54$ – $570$  kyr, albeit with large uncertainties (Fig. 4).

### Wurmbrandegga and Treskelen

At the Wurmbrandegga elevation transect, which is located  $\sim 12$  km up-fjord from Torbjørnsenfjellet and therefore must have deglaciated at or after  $17.4 \pm 1.5$  ka, six of seven  $^{10}\text{Be}$  ages are indistinguishable and indicate that this portion of Hornsund deglaciated at  $13.3 \pm 0.6$  ka (Figs 2 and 3). Unlike the Torbjørnsenfjellet transect, we find no evidence that the samples at Wurmbrandegga contain inherited  $^{10}\text{Be}$ , which is

suggestive of a greater total erosion depth than the Torbjørnsenfjellet site during periods of ice cover. Finally, our easternmost  $^{10}\text{Be}$  ages from perched boulders positioned  $\sim 13$  km up-fjord from Wurmbrandegga at Treskelen indicate that final deglaciation of the fjord occurred by  $13.0 \pm 0.7$  ka ( $n=3$ ) after removal of an older outlier ( $15.4 \pm 0.9$ ; Fig. 2). Combined, our  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  ages suggest that the Hornsund mouth deglaciated at  $17.4 \pm 1.5$  ka, with ice remaining near the fjord mouth for several thousand years before complete deglaciation between  $13.3 \pm 0.6$  and  $13.0 \pm 0.7$  ka (Figs 2 and 5). Alternatively, our ice-margin chronology allows for initial deglaciation of the Hornsund mouth at  $17.4 \pm 1.5$  ka followed by continued fjord deglaciation, an ice-margin re-advance beyond the Wurmbrandegga transect, followed by inner fjord deglaciation between  $13.3 \pm 0.6$  and  $13.0 \pm 0.7$  ka. However, we are unaware of any sediment packages within the fjord that are suggestive of a significant re-advance of the Hornsund glacier.

## The Hornsund outlet glacier during the last glacial cycle

### $^{10}\text{Be}$ and *in situ* $^{14}\text{C}$ ages versus traditional radiocarbon constraints

*In situ*  $^{14}\text{C}$  ages indicate that the Hornsund outlet glacier thinned  $\sim 400$  m at  $17.4 \pm 1.5$  ka, consistent with the timing of coastal deglaciation at Scottbreen ( $17.7 \pm 1.2$  ka), Fløyfjellet ( $15.7 \pm 0.7$  ka) and Torellbreen ( $15.9 \pm 1.6$  ka; Fig. 1). However, previously published records suggest that deglaciation of the western Svalbard coast occurred much later. A series of radiocarbon ages from marine sediments place the SBIS margin out on the shelf edge between  $\sim 23$  and  $20$  ka with deglaciation of the SW Spitsbergen coast constrained to  $\sim 13.7$ – $11.7$  cal ka BP based on minimum-limiting radiocarbon ages from raised marine sediments (Figs 1 and 2; Landvik *et al.*, 1998; Hormes *et al.*, 2013). It is possible that all of our deglaciation ages constrain initial ice-sheet thinning and unroofing of our sampling sites before deglaciation of the coastal lowlands. However, with the exception of the Torellbreen site located north of Hornsund, all of our

deglaciation ages span relatively low elevations that should capture the timing of coastal deglaciation (Table 1). Alternatively, there is a possible  $\sim 5$  kyr offset in the timing of Hornsund deglaciation as defined by our *in situ*  $^{14}\text{C}$  ages versus the minimum-limiting radiocarbon of 12.1 cal ka BP. And, the deglaciation age provided by the Wurmbrandegga elevation transect located only  $\sim 12$  km up-fjord from the outer coast is  $13.3 \pm 0.6$  ka;  $\sim 4$  kyr younger than the Hornsund mouth *in situ*  $^{14}\text{C}$  age, but still older than the minimum-limiting 12.1 cal ka BP deglaciation age. One explanation is that the minimum-limiting 12.1 cal ka BP age does not closely constrain the timing of deglaciation and that deglaciation occurred at either  $17.4 \pm 1.5$  ka or just before  $13.3 \pm 0.6$  ka. Or, the Hornsund outlet glacier thinned to at least 225 m asl at  $17.4 \pm 1.5$  ka (lowest sample in elevation transect) but occupied the fjord mouth for another several thousand years before final deglaciation. A final possibility is that our *in situ*  $^{14}\text{C}$  measurements contain inherited *in situ*  $^{14}\text{C}$  from a previous period of exposure that occurred before  $13.3 \pm 0.6$  ka or 12.1 cal ka BP.

### Modeling $^{10}\text{Be}$ and *in situ* $^{14}\text{C}$ inventories

To assess our measured  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  inventories at Torbjørnsenfjellet, we use the Svalbard glaciation curve over the last glacial cycle to model the possible  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  accumulation history at our sample sites. The Svalbard glaciation curve (Fig. 5) suggests a dynamic SBIS advanced onto the continental shelf several times over the last glacial cycle; between these glacial maxima, the SBIS retreated back to an ice configuration similar to today (Mangerud *et al.*, 1998; Eccleshall *et al.*, 2016; Figs 1 and 5). Notably, the SBIS occupied the shelf or shelf edge during MIS 6, MIS 5d, MIS 5b and MIS 2, with an additional, although probably not as extensive, advance during MIS 4. Although this Svalbard glaciation history is largely based on the Kapp Ekholm section at the head of Isfjorden (Fig. 1), a non-finite radiocarbon age of  $>40$  ka from shell fragments suggests that Hornsund may have deglaciated at least once before the most recent episode of deglaciation (Landvik *et al.*, 1998).

**Figure 4.** Measured  $^{26}\text{Al}/^{10}\text{Be}$  ratios against  $^{10}\text{Be}$  concentration at Torbjørnsenfjellet. Also plotted is the  $^{14}\text{C}$ -corrected  $^{26}\text{Al}/^{10}\text{Be}$  ratio for samples TORB-3 and TORB-4 using the average  $^{14}\text{C}$  age of  $17.4 \pm 0.7$  ka from the Torbjørnsenfjellet transect (i.e. the ratio at 17.4 ka). The present-day ratios for TORB-1 and TORB-2 ( $> 6.75$ ) suggest no previous sample burial. The corrected ratio for TORB-5 overlaps zero, which is due to subtracting more  $^{26}\text{Al}$  than was measured. However, the corrected  $^{10}\text{Be}$  concentration in TORB-5 suggests a small amount of previous exposure. [Colour figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

This template of SBIS advance and retreat provides a unique opportunity to assess the likelihood of our coastal Torbjørnsenfjellet bedrock sites yielding significant inherited  $^{10}\text{Be}$  coupled with *in situ*  $^{14}\text{C}$  inventories that have minimal or no inheritance. We assume no prior nuclide inventory at our bedrock sites at the termination of MIS 6 (Fig. 5). Next, we allow surface exposure and nuclide accumulation during MIS 5e, 5c, 5a and 3, burial and nuclide decay during MIS 5d, 5b, 4 and 2, and assume a 'true' deglaciation of  $\sim 13.3$  ka as defined by our nearby Wurmbrandegga  $^{10}\text{Be}$  ages. We want to assess the maximum amount of potential inherited nuclides at Torbjørnsenfjellet so we assume no bedrock erosion during periods of ice cover; only nuclide decay via burial decreases the nuclide inventory. When modeling  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  concentrations using these assumptions, our Torbjørnsenfjellet bedrock sites would have  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  concentrations equating to exposure ages of  $\sim 81$  and 14.6 ka, respectively (Fig. 5).

Our model suggests that using the Svalbard glaciation curve as a template for surface exposure and burial results in  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  concentrations similar to what we measured – old  $^{10}\text{Be}$  ages coupled with younger *in situ*  $^{14}\text{C}$  ages. In addition, our approach results in a small amount of inherited *in situ*  $^{14}\text{C}$  at our Torbjørnsenfjellet sample sites. Rather, the modeled duration of MIS 2 burial is not long enough to

completely remove the accumulated MIS 5e to MIS 3 inventory of *in situ*  $^{14}\text{C}$  (Fig. 5). Because the duration of MIS 2 burial results in a small amount of inherited *in situ*  $^{14}\text{C}$  in our model experiment, we next assume that our measured *in situ*  $^{14}\text{C}$  concentrations are influenced by inheritance and then calculate the timing of deglaciation needed to result in our measured *in situ*  $^{14}\text{C}$  concentrations. With this approach, our measured *in situ*  $^{14}\text{C}$  concentrations are achieved if deglaciation occurs at  $\sim 15.6$  ka, which is suggestive of a 'true' deglaciation age that is  $\sim 2$  ka younger than our measured *in situ*  $^{14}\text{C}$  ages. However, our model set up is tuned to allow for the maximum amount of inherited *in situ*  $^{14}\text{C}$  because we assume no glacial erosion during periods of ice cover, which is not supported by our measured  $^{10}\text{Be}$  ages, which vary across the transect and imply varying degrees of glacial erosion. The modeled exposure–burial histories result in  $^{10}\text{Be}$  concentrations that equate to  $\sim 81$ – $85$  ka, whereas our measured  $^{10}\text{Be}$  ages from the Torbjørnsenfjellet transect range from  $\sim 16$  to  $\sim 36$  ka (Fig. 3C). This disparity between the modeled and measured  $^{10}\text{Be}$  ages suggests that the Torbjørnsenfjellet sample sites either experienced some degree of glacial erosion that stripped away  $^{10}\text{Be}$  (and *in situ*  $^{14}\text{C}$ ) from the bedrock sites and/or our sample sites experienced less surface exposure during the last glacial cycle than what we modeled using the Svalbard glaciation curve.

**Figure 5.** (A) Svalbard glaciation curve (Mangerud *et al.*, 1998; Eccleshall *et al.*, 2016). The timing of glacier advance has been tuned to coincide with the Marine Isotope Stage (MIS) that each advance is thought to correlate to as discussed in Eccleshall *et al.* (2016). MIS definitions are from Lisiecki and Raymo (2005). Pls-D: Phantomodden interstadial D; G-E: Glaciation E; KElS-F: Kapp Ekholm interstadial F; Ig-H: interglaciation H. Shown are the modeled proof-of-concept  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  concentrations at 252 m asl (TORB-3) assuming that our Torbjørnsenfjellet sample sites become exposed and buried following the Svalbard glaciation curve and assuming a 'true' deglaciation age of 13.3 ka. The resulting *in situ*  $^{14}\text{C}$  concentration equates to an exposure age of  $\sim 14.6$  ka. (B) Retreat chronologies for the Hornsund and Isfjorden sectors of the SBIS compared to the NGRIP  $\delta^{18}\text{O}$  record (North Greenland Ice Core Project members, 2004) and a record of ice-rafted detritus and  $\delta^{18}\text{O}$  (*N. pachyderma* s.) from core JM03-373PC2 located south-west of Hornsund (Rasmussen *et al.*, 2007; Jessen *et al.*, 2010; see location No. 2 on Fig. 1). Numbers between data points are the calculated net (minimum) ice-margin retreat rates using the age constraint midpoint. Symbols are larger than the uncertainties with the exception of the *in situ*  $^{14}\text{C}$ -based Torbjørnsenfjellet data point at  $17.4 \pm 1.5$  ka. The JM03-373PC2 age model has been recalibrated using Calib 7.1 and a reservoir correction of 440 years (Stuiver *et al.*, 2018; see Rasmussen *et al.*, 2007 and Jessen *et al.*, 2010 for details). [Colour figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

**Table 4.** Summary of deglacial radiocarbon ages.

All radiocarbon ages were calibrated with Calib 7.1 and the Marine13 database (Stuiver *et al.*, 2018), and use a  $\Delta R$  value of  $107 \pm 52$  years (Mangerud *et al.*, 2006; Hormes *et al.*, 2013). Calibrated ages and their uncertainties have been rounded to the nearest decade. Note that locations marked with an asterisk report <sup>10</sup>Be ages and are reported as years of exposure, not years BP, and have been re-calculated using v3 of the exposure age calculator found at <https://hess.ess.washington.edu/> (see main text).

The minor differences in our measured versus modeled  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  inventories is probably due to variable glacial erosion during periods of ice cover and/or uncertainty in the exact duration that our bedrock sites experienced ice cover and nuclide decay versus the exact duration of ice-free conditions and nuclide accumulation. Despite these differences, our model captures the overall pattern of older  $^{10}\text{Be}$  ages influenced by isotopic inheritance coupled with *in situ*  $^{14}\text{C}$  ages that are much younger. The maximum inheritance scenario that does not account for glacial erosion results in *in situ*  $^{14}\text{C}$  concentrations with only a small degree of inheritance ( $\sim 2$  ka). Glacial erosion during periods of ice cover, as suggested by the spread in  $^{10}\text{Be}$  ages, would not only remove a portion of previously accumulated  $^{10}\text{Be}$ , but also remove *in situ*  $^{14}\text{C}$  resulting in bedrock sample sites that do not contain previously accumulated  $^{14}\text{C}$  before the most recent period of exposure. Thus, it is unlikely that our *in situ*  $^{14}\text{C}$  ages are influenced by inheritance and that the 'true' age of deglaciation at the fjord mouth is  $17.4 \pm 1.5$  ka (Fig. 2).

## Coastal deglaciation of western Spitsbergen

Our  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  ages indicate that the region of coastal south-western Spitsbergen south of Isfjorden deglaciated between  $\sim 18$  and  $16$  ka (Fig. 1). This timing of coastal deglaciation in south-western Spitsbergen is broadly consistent with the timing of coastal deglaciation in north-western Spitsbergen, which is constrained to  $\sim 17.9$ – $15.6$  cal ka BP based on the oldest published coastal radiocarbon ages, and low-elevation  $^{10}\text{Be}$  ages from the region (Fig. 1; Table 4). Although several older  $^{10}\text{Be}$  ages from north-western Spitsbergen range from  $\sim 25.0$  to  $19.3$  ka (Fig. 1), these ages are mainly from high-elevation nunataks and probably record initial ice sheet thinning rather than coastal deglaciation. Two older  $^{10}\text{Be}$  ages of  $26.7 \pm 3.9$  and  $28.3 \pm 2.1$  ka from erratics in Nordaustlandet may record the timing of early coastal deglaciation considering their low elevations ( $165$  and  $123$  m asl), but their anomalously old ages could simply represent the presence of cold-based ice and  $^{10}\text{Be}$  inheritance as suggested by the original authors (Hormes *et al.*, 2011; Fig. 1; Table 1). It appears that the timing of coastal deglaciation in north-western and south-western Spitsbergen (between Hornsund and Scottbreen) is perhaps similar, but deglaciation through the Isfjorden trough occurred much later (Figs 1 and 5). A relatively dense transect of radiocarbon ages extending from the outer shelf to near the modern ice margin in Isfjorden indicates that although the timing of initial retreat from the shelf edge is similar to the timing of initial ice-margin retreat west of Hornsund ( $\sim 23$  ka), ice at Isfjorden remained near the shelf edge until as late as  $\sim 17.9$  cal ka BP (Fig. 1). In addition, the Isfjorden mouth did not deglaciate until  $\sim 14.3$  cal ka BP,  $1.5$ – $3.5$  kyr later than the timing of coastal deglaciation in south-western Spitsbergen (Fig. 1). A record of ice-rafted detritus (IRD) located immediately south-west of Hornsund reveals peaks in IRD at  $\sim 18.7$  and  $\sim 16.3$  ka, suggestive of increased calving and ice-margin retreat at these times (Fig. 5; Rasmussen *et al.*, 2007; Jessen *et al.*, 2010). This increase in IRD deposition is broadly correlative with the timing of coastal deglaciation as constrained by our  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  measurements ( $\sim 18$ – $16$  ka); however, the resolution of our record, and in particular *in situ*  $^{14}\text{C}$ -based age of deglaciation ( $17.4 \pm 1.5$  ka), prevents us from linking the timing of deglaciation to any one IRD peak (Fig. 5).

The timing of coastal deglaciation appears to have differed between Isfjorden and south-western Spitsbergen, but the relatively sparse number of radiocarbon constraints between

the outer shelf and coast at Hornsund prevents us from determining if ice in this sector stayed near the shelf edge for several thousand years or gradually retreated between  $\sim 23$  and  $17.4 \pm 1.5$  ka (Figs 1 and 5). Existing age constraints from Isfjorden and Hornsund allow us to place millennial- to centennial-scale retreat of the ice margin into a long-term context (Fig. 5). At Hornsund, the SBIS retreated at a millennially averaged rate of  $\sim 10$  m  $\text{a}^{-1}$  between  $\sim 23$  and  $17.4$  ka, and  $\sim 3$  m  $\text{a}^{-1}$  between  $17.4$  and  $13.3$  ka. However, the  $17.4 \pm 1.5$  ka constraint along the Hornsund transect at Torbjørnsenfjellet requires  $\sim 400$  m of ice-sheet thinning in addition to constraining the lateral retreat of the ice margin. Following deglaciation at Wurmbrandegga, the ice margin retreated between  $\sim 13.3$  and  $13.0$  ka at a rate of  $\sim 43$  m  $\text{a}^{-1}$  (Fig. 5). At Isfjorden, initial ice-margin retreat occurred at  $\sim 3$  m  $\text{a}^{-1}$  between  $23.2$  cal ka BP and  $17.9$  cal ka BP followed by a slightly faster rate of retreat of  $\sim 13$  m  $\text{a}^{-1}$  between  $\sim 17.9$  and  $14.5$  cal ka BP. Afterwards, retreat rates increased significantly between  $\sim 14.5$  and  $14.3$  cal ka BP ( $\sim 400$  m  $\text{a}^{-1}$ ), with another pulse of rapid deglaciation centered on  $\sim 12.3$  cal ka BP ( $\sim 120$  m  $\text{a}^{-1}$ ; Fig. 5). We note that these retreat rates should be considered minimum or net retreat rates because our methods are limited in their ability to identify pulses of fast ice retreat and almost certainly smooth over episodes of faster ice retreat.

It appears that initial retreat of the western margin of the SBIS occurred as early as  $\sim 23$  ka, synchronous with the initial rise in boreal summer insolation at  $\sim 24$ – $23$  ka and consistent with the onset of initial retreat of the southern margin of the Laurentide Ice Sheet (e.g. Ullman *et al.*, 2015), but pre-dating any significant rise in eustatic sea level. However, SBIS retreat rates remained relatively slow until at least  $17.9$  ka and perhaps as late as  $\sim 14.5$  ka as suggested by the Isfjorden recession chronology. Indeed, whereas initial retreat was contemporaneous with rising summer insolation, elevated retreat rates were not achieved until several millennia later, contemporaneous with rising temperatures as recorded in Greenland ice cores at the onset of the Bølling–Allerød (Fig. 5).

## Conclusions

Deglaciation of the south-western Spitsbergen coast probably occurred between  $\sim 18$  and  $16$  ka based on new  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  measurements from four separate sites along  $\sim 60$  km of south-western Spitsbergen.  $^{10}\text{Be}$  measurements in bedrock along a  $\sim 400$ -m elevation transect display varying amounts of isotopic inheritance and are unable to constrain the timing of deglaciation or ice-sheet thinning, but complimentary *in situ*  $^{14}\text{C}$  measurements are statistically identical and mark an episode of ice-sheet thinning at  $17.4 \pm 1.5$  ka. Following coastal deglaciation, the middle of Hornsund deglaciated by  $13.3 \pm 0.6$  ka with complete fjord deglaciation by  $13.0 \pm 0.7$  ka. Our dataset indicates that the timing of coastal deglaciation in south-western Spitsbergen was significantly earlier than previous estimates based on a limited number of minimum-constraining radiocarbon ages. Previously published age constraints, coupled with our new  $^{10}\text{Be}$  and *in situ*  $^{14}\text{C}$  ages, suggest that the western coast of Spitsbergen between Hornsund and Scottbreen deglaciated between  $\sim 18$  and  $16$  ka, and that deglaciation of Isfjorden occurred much later with the fjord mouth deglaciating at  $\sim 14.3$  ka. Initial retreat of the western SBIS margin appears to have occurred at  $\sim 23$  ka followed by relatively variable and asynchronous retreat between the Isfjorden and Hornsund sectors of the SBIS, thus highlighting the dynamic nature in which ice sheets recede. Lastly, *in situ*  $^{14}\text{C}$  measurements offer the

ability to rectify ambiguous  $^{10}\text{Be}$ -based datasets influenced by isotopic inheritance in order to extract key chronological information.

**Acknowledgements.** We are grateful for logistical support from the Polish Polar Station at Hornsund and two Arctic field grants to Endre Gjermundsen from the Svalbard Science Forum by the Norwegian Research Council. A portion of this work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under contracts DE-AC52-07NA27344. Fieldwork would not have been possible without the help of Ellinor Falkgjerdet, Lina Gislefoss, Carl Petter Nielsen and Bjørn André Skjæret. We thank one anonymous reviewer for several suggestions that helped improve the manuscript. This is LDEO contribution #8225 and LLNL-JRNL-743296.
